We investigate a small vortex-lattice system of four corotating vortices in an atomic Bose-Einstein condensate and find that the vortex dynamics display chaotic behavior after a system quench introduced by reversing the direction of circulation of a single vortex through a phase-imprinting process. By tracking the vortex trajectories and Lyapunov exponent, we show the onset of chaotic dynamics is not immediate, but occurs at later times and is accelerated by the close approach and separation of all vortices in a scattering event. The techniques we develop could potentially be applied to create locally induced chaotic dynamics in larger lattice systems as a stepping stone to study the role of chaotic events in turbulent vortex dynamics.
vortices, with two corotating vortices and an antivortex rotating in the opposite direction has also been explored theoretically through a reduced Hamiltonian approach \[11,12\].

Vortex dynamics in superfluid systems draw remarkable analogies to classical point-vortex systems and classical vortex turbulence in spite of the striking differences between quantum and classical fluids. In BECs, the superfluid velocity, \( \mathbf{v} = \bar{\hbar} \nabla \theta / m \), is dependent purely on the gradient of the condensate phase \( \theta \), which means quantum vortices possess a well-defined strength and quantized circulation, making them simpler than their classical counterparts which can be of any strength and arbitrary circulation. Although quantum and classical vortices are very different, hallmarks of classical turbulence, such as the Kolmogorov spectrum, have been shown to emerge in quantum vortex turbulence on scales larger than the average intervortex spacing \[14–17\]. Vortex turbulence in two-dimensional BECs has become a subject of increasing experimental interest, due to the controllable nature of BECs and quantum vortices. Experimental techniques have advanced, resulting in accessible methods to detect vortex circulation \[18\], image vortices \textit{in-situ} \[19\], and build a picture of vortex dynamics at different times in a single experiment \[20,21\]. Recent times have seen experiments exhibiting the von Kármán vortex street \[22\], as well as investigations into decaying two dimensional turbulence \[23,24\] and demonstration of Onsager vortex clusters \[25,26\] in Bose-Einstein condensates.

In this work we will exploit the finely controllable nature of vortices in BECs to extend the picture of chaotic vortex dynamics in systems consisting of small numbers of quantum vortices. Vortex lattices in rotating BECs are extremely robust and have proven to be stable against externally applied perturbations, such as periodic kicking \[27\]. One way to capitalise on this stability and generate repeatable and well-controlled initial conditions is to engineer lattice defects by applying the technique of phase imprinting. Phase imprinting can be used to control both the number and location of defects in vortex lattices \[28\] and is also experimentally feasible \[29\]. Phase imprinting has been applied in a variety of BEC experiments, ranging from transferring orbital angular momentum to atoms from a Laguerre-Gaussian beam \[30,31\], to using a pulsed light shift with a tailored intensity pattern to create a soliton \[32\], vortex \[29\], or states with quantized circulation \[33\].

In the following, we show that phase imprinting one vortex defect in a small vortex lattice system can be used to controllably create chaotic vortex dynamics in an experimentally accessible way. We also find that even though chaotic dynamics is confirmed by a positive Lyapunov exponent immediately after the quench, other signals of chaotic dynamics are boosted only at later times by the close approach and consequent scattering of all vortices. Applying this technique to more than one vortex in the lattice may potentially be used to induce chaotic vortex dynamics in systems of larger numbers of vortices, enabling one to control the number of vortices with chaotic trajectories and the location of locally induced vortex chaos in larger lattice systems.

This manuscript is organized as follows. In Sec. II we discuss the theoretical model we apply to study the small vortex lattice systems in BECs, introducing the Gross-Pitaevskii equation and describing the technique of phase imprinting. Section III presents the resulting condensate dynamics after phase imprinting, and discusses how this leads to regular and chaotic vortex dynamics in systems of four corotating vortices and three corotating vortices and one antivortex, respectively. In Sec. IV, by tracking vortex trajectories and calculating the Lyapunov spectrum, we further quantify the onset of chaos. Finally, our conclusions are presented in Sec. V.

II. THEORETICAL MODEL

The dynamics of vortices in a BEC near zero Kelvin are well described in the mean-field regime by a two-dimensional Gross-Pitaevskii equation (GPE), which can be written as

\[
\imath \hbar \frac{\partial}{\partial t} \Psi = \left( -\frac{\hbar^2}{2m} \nabla^2 + \frac{1}{2} m \omega^2 r^2 + g|\Psi|^2 - \Omega L_z \right) \Psi, \tag{1}
\]

054701-2
in the rotating frame. Here $L_z = x p_y - y p_x$ is the angular momentum operator, and we choose a realistic value of $\Omega = 0.3 \times 2\pi$ Hz as the frequency of an externally applied rotation around the $z$ axis. We model a condensate of $N = 10^6$ $^{87}$Rb atoms with an s-wave scattering length $a_s \approx 90 a_0$, confined in an oblate harmonic trapping potential, $(V_\perp, V_z) = \frac{1}{2} m (\omega_\perp^2 r^2, \omega_z^2 z^2)$, with typical trapping frequencies $(\omega_\perp, \omega_z) = (2\pi, 32\pi)$ Hz and $\mathbf{r}$ is a position vector. The effective two-dimensional interaction strength is $g = (4\pi \hbar^2 a_s N/m) \sqrt{m \omega_z / 2\pi \hbar} = 6.8 \times 10^{-40} m^4 kg/s^2$.

For the evolution of our BEC system, we use the split-step method [34]. In order to find the ground states in the rotating frame, we employ imaginary time propagation by substituting $t = -i \tau$ in Eq. (1) [35]. We then solve this equation efficiently on a spatial grid of $2^{10} \times 2^{10}$ points covering an extent of $700 \mu m \times 700 \mu m$, using graphics processing units (GPUs) by making use of the open-source GPE solver, GPUE [36].

Under large, externally imposed rotation, the ground state of a BEC can consist of a triangular lattice of quantum vortices, with the number of constituent vortices dependent on the rotation strength [37–39]. However, for smaller rotation strengths other configurations are known [40] and we will concentrate on the regime where four vortices appear in the ground state in a square configuration [41]. While the direction of rotation of the individual vortices is usually the same as that of the applied external rotation, this can be changed by phase imprinting [28].

Through phase imprinting, a phase profile corresponding to a vortex with $2\pi$ phase winding can be introduced into the condensate by $\Psi_{\text{IMP}}(\mathbf{r}, t) = |\Psi(\mathbf{r}, t)| \exp[i\theta_{\text{IMP}}(\mathbf{r})]$ where the four-quadrant arctan defines $\theta_{\text{IMP}}(\mathbf{r}) = \arctan(y - y_0, x - x_0)$, which centers the singularity of the vortex phase profile at the position $(x_0, y_0)$ in the condensate. Imprinting a phase mask of $2\pi$ winding centered on an existing vortex of $2\pi$ winding in the same direction will create a doubly charged vortex (of $4\pi$ winding) at that location, which will subsequently decay into two singly charged vortices [42]. Imprinting a vortex-centered phase mask of $2\pi$ winding in the opposite direction to the vortex circulation will result in vortex annihilation [see Fig. 1(a)], removing the circulation in that region. Finally, imprinting a phase mask with $4\pi$ winding in the opposite direction to the direction of circulation of a vortex on that vortex center [see Fig. 1(b)] will reverse the direction of circulation of that vortex. To annihilate or change the direction of circulation of a vortex through phase imprinting, the imprinted phase mask must be centered on a vortex in the lattice close to the vortex core at a distance of less than twice the condensate healing length [28].
FIG. 2. Histograms of the positions of each vortex in the x-y plane, tracked over an evolution time of 20 s in the corotating frame. The vortex in the lower left has been annihilated by phase imprinting and reimprinted with (a) the same and (b) the opposite direction of rotation, exactly on the vortex core. The area of each plot is 400 μm × 400 μm, and the white circles are contour lines at 40% of the maximum density, indicating extent of vortex motion for a rotationally symmetric condensate. (a) For four vortices with the same circulation direction, regular trajectories at constant radius appear, while in panel (b), disordered vortex trajectories can be seen.

III. REGULAR AND IRREGULAR VORTEX DYNAMICS

In this work, we reverse the direction of circulation of a single vortex in a lattice through phase imprinting and investigate if the resulting vortex dynamics are regular or chaotic. To engineer slightly different initial conditions, we vary the distance from the existing vortex core at which the phase imprint has its singularity, while staying within a healing length, and compare the resulting trajectories. It is well established that a lattice of vortices with the same direction of rotation exhibits regular dynamics [39], and in Fig. 2(a) we confirm this for a system of four vortices. The graphs show the histograms of the positions of each individual vortex (labeled 0 to 3 from left to right), where vortex 0 has been erased and reimprinted with the original winding. One can clearly see that they remain stationary in the corotating frame over 20 s of evolution, even though a small residual movement from their initial position arises, which stems from the presence of small phonon excitations that were not fully damped out in the numerical ground-state finding process. However, when the direction of circulation of a single vortex is reversed in the reimprinting process, this regularity disappears, and the vortex dynamics become more disordered, with vortices traversing the width of the condensate [shown in Fig. 2(b)], where the heavily weighted histogram cells indicate more likely vortex positions during evolution. Reversing the direction of rotation of a single vortex can therefore lead to dramatically different results. It is worth noting that such histograms of vortex position evolution could readily be constructed in experiments with available in-situ imaging techniques [19,20].

Although introducing an antivortex results in disordered dynamics, one could imagine that this disordered motion is irregular but stable, and any small perturbation in vortex position might give rise to the same irregular trajectories around the condensate. To check this we compare two sets of perturbed vortex trajectories with slightly different shifts in the initial position of the antivortex, r₀ and r′₀, and show the differences in trajectories defined as Δrᵢ(t) = rᵢ(t) − r′ᵢ(t) in Fig. 3, where r refers to the position of the iᵗʰ vortex from the center of the condensate and i ∈ {1, 2, 3} corresponds to the vortex number. One can see that this difference is initially small, but starts to diverge significantly at around t ≈ 10 s, which is a strong indication of chaotic dynamics in this system.
CHAOTIC FEW-BODY VORTEX DYNAMICS IN ROTATING …

FIG. 3. Evolution of the difference in trajectories $\Delta \mathbf{r}_i = \mathbf{r}_i - \mathbf{r}'_i$ with $\mathbf{r}$ corresponding to the position of the $i$th vortex from the center of the condensate and $i \in \{0, 1, 2, 3\}$ labeling each individual vortex for the four-vortex system as shown in Fig. 2. A small change in the initial position of the antivortex arises from a phase imprint at $(x_0, y_0)$ and $(x_0 - \xi/3, y_0)$ where $(x_0, y_0)$ denotes the the preexisting corotating vortex core position. The curves show that even though the onset of disorder is immediate, a strong divergence of trajectories is observed at about $t \approx 10$ s (see projections onto the $x$-$t$ and $y$-$t$ planes). The difference in trajectory of the antivortex, $\Delta \mathbf{r}_0$, is shown in blue, while yellow, orange, and purple lines depict the three corotating vortices.

A close inspection of the vortex dynamics (see supplemental movie [43]) shows that the strong divergence in trajectories appears to be accelerated when all four vortices move close to each other and are minimally separated. Because the velocity fields of each vortex decays as $1/r$, where $r$ is the distance from each vortex core, the vortices experience stronger velocity fields when they are closer to each other; moreover, the point of minimal separation can be interpreted as a multivortex scattering event. Such a scattering event is highly nonlinear and accelerates the divergence between the vortex trajectories. In Fig. 4 we show snapshots of the full condensate density before ($t = 6$ s), at ($t = 10$ s) and after ($t = 15$ s) the scattering event. One can see that the differences between $\Delta x = 0$ [Fig. 4(a)] and $\Delta x = \xi/3$ [Fig. 4(b)] are small before, but large after multivortex scattering. By tracking the distance between each corotating vortex and the antivortex, we show in Fig. 4(c) that a clear minimum around $t = 10$ s exists, indicating vortex scattering at this time. In our calculations, we track vortex positions numerically, by finding the positions in the condensate where the condensate density $|\Psi|^2$ goes to zero, with a $2\pi$ winding in the condensate phase around the grid plaquette surrounding that position, signaling the position of a vortex. As long as the distance between two vortices is large, the velocity field of one vortex seen by the other vortex will be small, and consequently any small difference stemming from the small change in the initial condition will not have a large effect on the vortex dynamics. However, a closer approach of the vortex cores leads to stronger interactions and therefore differences in the velocity fields have a larger influence on the ensuing vortex dynamics, leading to the observed boost in the divergence of the resulting trajectories. In order to determine if this disordered motion is indeed chaotic, it is necessary to analyze the vortex dynamics in more detail and to do this we proceed to calculate the Lyapunov exponent.

IV. CHARACTERIZING CHAOTIC VORTEX DYNAMICS

Lyapunov exponents give the rates of divergence of nearby orbits in phase space [44]. For the two neighboring trajectories in four-dimensional phase space we consider, $\mathbf{P}(t) = (x(t), y(t), v_x(t), v_y(t))$ and $\mathbf{P}'(t) = (x'(t), y'(t), v'_x(t), v'_y(t))$, with separation defined as $\delta \mathbf{P}(t) =$
FIG. 4. Density plots of condensate for (a) \( \Delta x = 0 \) and (b) \( \Delta x = \xi/3 \) at times \( t = \{6, 10, 15\} \) s. The densities before the scattering event differ only on small scales (see \( t = 6 \) s), whereas for times after the event large deviations are visible (see \( t = 15 \) s). At \( t = 10 \) s the vortices make their closest approach. The area plotted is 500 \( \mu m \times 500 \mu m \). (c) Distances between the vortices at positions \( r_i \) with \( r \) corresponding to the position of the \( i \)th vortex from the center of the condensate and \( i \in \{1, 2, 3\} \) corresponding to the vortex number as shown in Fig. 2 and antivortex at \( r_0 \) for \( \Delta x = 0 \). A minimum around \( t = 10 \) s is clearly visible.

\[
\left( \delta x(t), \delta y(t), \delta v_x(t), \delta v_y(t) \right)
\]
where \( \delta x(t) = x(t) - x'(t) \), etc. The resulting four-dimensional Lyapunov exponent, \( \lambda \), can then be calculated as

\[
\lambda = \lim_{t \to \infty} \frac{1}{t} \ln \frac{||\delta P(t)||}{||\delta P(0)||},
\]

where \( || \cdot || \) denotes the Euclidean norm. If one or more Lyapunov exponents are positive, the system is chaotic, with unpredictable dynamics developing at a timescale which can be determined from the magnitude of the Lyapunov exponent. While it is difficult numerically to isolate the evolution of the momentum of each vortex in time, we can build up a representative picture of the phase-space trajectories of individual vortices in our vortex system by tracking both the position and velocity of each vortex. The Lyapunov exponents can then be calculated by comparing two trajectories with slightly perturbed initial conditions.

In order to define a phase-space measure for the total system of vortices instead of for each constituent vortex individually, we use a center of mass (COM) variable defined by \( R_M = \frac{1}{n+1} \sum_{i=0}^{n} r_i \), where \( n+1 \) is the number of vortices. Similarly, the center of mass velocity is expressed as \( v_M = \frac{1}{n+1} \sum_{i=0}^{n} v_i \). To calculate the Lyapunov exponent using the center of mass variables in Eq. (2), we define the separation of the trajectories in four-dimensional phase-space as \( \delta P(t) = (\delta x_M(t), \delta y_M(t), \delta v_{Mx}(t), \delta v_{My}(t)) \) where \( \delta x_M(t) = x_M(t) - x'_M(t) \), etc.
FIG. 5. The insets show the histograms of the COM trajectories calculated over 20 s of evolution for the system of four vortices when the position of a single vortex has been shifted by $\Delta x = 0 \xi$ and $\Delta x = \xi/3$. The upper two panels depict the corresponding trajectories after the direction of rotation of a single vortex has been reversed, whereas the lower row displays the trajectories for the case where all vortices corotate. The main curve plots the corresponding Lyapunov exponents, calculated from the shown COM trajectories. The negative Lyapunov exponents (orange) indicate that shifting the vortex about the initial position still ensures the stability of vortex trajectories. Reversing the direction of circulation of a single vortex (blue) however leads to fluctuations about zero, eventually leading to a fully positive exponent.

The insets of Fig. 5 show the histogram in time (and in the corotating frame) of the center of mass trajectories, which confirm similar irregular dynamics of the system with the antivortex (upper row) and regular trajectories of the system with four corotating vortices (lower row). It is worth noting that one could also consider using a global measure which takes into account the direction of circulation of the vortices, and instead consider a center of charge variable [11]. As we find both quantities give similar qualitative results for calculating the Lyapunov exponents, we only consider the COM of the vortex system here.

As expected, this COM Lyapunov exponent spectrum, calculated for both regular and disordered four vortex systems, shows that the regular corotating system always maintains a negative value for the Lyapunov exponent, indicating nonchaotic behavior (orange curve in Fig. 5). However, for the system where a vortex of opposite sign is introduced, we observe that the Lyapunov exponent initially strongly oscillates but later settles and grows to maintain a positive value, indicating chaotic behavior. The time of onset of the constantly positive exponent corresponds to the appearance of the scattering event and the boost in the difference in trajectories. The strong oscillations before that time can therefore most likely be attributed to the finite resolution of our numerics and consequently limited accuracy of the vortex velocities. Such a Lyapunov exponent spectrum could be experimentally constructed through in-situ measurements [19,20], where vortex positions (and consequently velocities) are tracked in a single experimental run.

V. DISCUSSION AND CONCLUSIONS

We have demonstrated that applying phase imprinting techniques to a small lattice of vortices can change the dynamics of the system from being regular to being chaotic. By simply reversing
the direction of rotation of a single vortex, the Lyapunov exponent of the COM trajectories for
the vortices clearly indicates the chaotic nature of the vortex trajectories after an initial adjustment
phase. In fact, we have found that the chaotic dynamics are accelerated at late times by the close
approach and consequent scattering of vortices in a multivortex scattering event. This scattering
event amplifies the small initial difference in trajectories and results in vortices scattering at different
angles while also seeding the ensuing chaotic divergence of trajectories. This method is potentially
scalable to larger lattices of vortices and is realisable in cold-atom experiments.

We have also checked that reversing the direction of circulation of a single vortex in small
lattices of five and six vortices still exhibit chaotic dynamics [45], and find they exhibit a similar
degree of chaotic motion with Lyapunov exponents of 0.24, 0.24, and 0.27 for the four, five and six
vortex cases, respectively after 20 s of evolution. This result contrasts to the limit of rapidly rotating
condensates, where large Abrikosov vortex lattices develop and phase engineering a single vortex
defect is known to only induce localized disturbance [28]. Studying this crossover from chaotic to
regular dynamics, and engineering a crossover from regular to turbulent dynamics is an exciting
extension we leave to future work.
